elbansarkhani@cdc.informatik.tu-darmstadt.de

Abstract Lattice-based encryption schemes still suffer from a low message throughput per ciphertext and inefficient solutions towards realizing enhanced security properties such as CCA1- or CCA2-security. This is mainly due to the fact that the underlying schemes still follow a traditional design concept and do not tap the full potentials of LWE. Furthermore, the desired security features are also often achieved by costly approaches or less efficient generic transformations. Recently, a novel encryption scheme based on the A-LWE assumption (relying on the hardness of LWE) has been proposed, where data is embedded into the error term without changing its target distributions. By this novelty it is possible to encrypt much more data as compared to the classical approach. In this paper we revisit this approach and propose several techniques in order to improve the message throughput per ciphertext. Furthermore, we present a very efficient trapdoor construction of reduced storage size. More precisely, the secret and public key sizes are reduced to just 1 polynomial, as opposed to $O(\log q)$ polynomials following previous constructions. Finally, we give an efficient implementation of the scheme instantiated with the new trapdoor construction. In particular, we attest high message throughputs and low ciphertext expansion factors at efficient running times. Our scheme even ensures CCA (or RCCA) security, while entailing a great deal of flexibility to encrypt arbitrary large messages or signatures by use of the same secret key.

Keywords: Lattice-Based Encryption, Lattice-Based Assumptions

1 Introduction

In [EDB15], a novel lattice-based encryption scheme has been proposed that encrypts data in a way that differs from previous constructions [Reg05, GPV08, Pei09, Pei10, ABB10, LP11, SS11, MP12] following the one-time-pad approach. It is equipped with many features such as a high message throughput per ciphertext as compared to current state-of-the-art encryption schemes while simultaneously ensuring different security notions (e.g. CCA security) for many
cryptographic applications, for instance utilized for sign-then-encrypt scenarios or to securely transmit bundles of keys as required for the provisioning of remote attestation keys during manufacturing. Public key encryption schemes also represent important building blocks of advanced primitives such as group signature and ABS schemes. In many application scenarios it is also desired to ensure CCA1- or CCA2-security. The Augmented Learning with Errors problem (A-LWE) [EDB15], a modified LWE variant, has been introduced that allows to inject auxiliary data into the error term without changing the target distributions. In fact, the A-LWE problem has been proven to be hard to solve in the random oracle model assuming the hardness of LWE. Using a suitable trapdoor function as a black-box such as [EB14, MP12], the owner of the trapdoor is empowered to recover the secret resp. error-term and hence reveal the injected data. By this novelty, it is possible to exploit the error term as a container for the message or further information such as lattice-based signatures following the distributions of the error-term. It further encompasses a great deal of flexibility and other important properties such as CCA-security.

1.1 Our Contributions

In this paper we revisit the A-LWE problem and the implied encryption schemes from [EDB15]. In particular, we provide several theoretical improvements, introduce new tools, and give an efficient software implementation of the scheme testifying its conjectured efficiency. Below, we give an overview of features that can be realized by our scheme **LARA** (LAttice-based encryption of data embedded in RAndomness):

1. **Flexibility.** The encryptor of the scheme can increase the amount of encrypted data without invoking the encryption engine several times. Since the message is embedded into the error term, increasing the error size (to at most $\|\mathbf{e}\|_2 < q/4$ depending on the parameters) results in a higher message throughput. Thus, we achieve very low ciphertext expansion factors as compared to recent schemes. Furthermore, using a trapdoor allows to retrieve the secret and error polynomials for inspection. The retrieved secret polynomial could also play the role of a uniform random key for a symmetric key cipher.

2. **Signature embedding.** Due to the coinciding distributions of the error term and lattice-based signatures, the encryptor can exploit the signature as the error term. For instance, $(\mathbf{c}_2, \mathbf{c}_3)$ contains the signature on the error or message encrypted in $\mathbf{c}_1$. This offers an CCA2 like flavour as the decryptor can verify that the ciphertext has not been altered during transmission and the source of the data is authenticated via the signature. In case the size of the signature is too large, the encryptor can further exploit its flexibility.

3. **Security.** An increase of the error size already enhances the security of the scheme. However, it is also possible to further lift the security from CPA or CCA1 to RCCA or CCA2 almost for free via the transformations from [EDB15].
4. **Efficiency.** Due to the resemblance of ciphertexts to plain LWE samples, the efficiency of the scheme is very close to that required to generate ring-LWE samples, which intuitively seems to be a lower bound for many encryption schemes that are based on ring-LWE.

**Improved Message Throughput.** We introduce new techniques in order to increase the message throughput per ciphertext. In fact, we are able to exploit almost the full min-entropy of the error term to embed arbitrary messages. Previously, only one bit of the message was injected into a coefficient of the error term. By our new method, we are able to inject about $\log_2(\alpha q/\omega(\sqrt{\log n}))$ bits per entry for an error vector sampled according to the discrete Gaussian distribution with parameter $\alpha q$. Encoding and decoding of the message requires only to reduce the coefficients modulo some integer.

Following this approach we can revise the parameters from [EBB15] according to the table above. When comparing our approach with the CPA-secure encryption scheme from Lindner and Peikert [LP11] and other recently proposed schemes, we attest an improvement factor of at least $O(\log(\alpha q))$.

**Improved Trapdoors, Scheme Instantiation and Security.** We give an improved construction of trapdoors in the random oracle model, which allows to significantly reduce the number of ring elements in the public key by a factor $O(\log q)$, hence moving trapdoor constructions towards practicality. More precisely, we give an improved construction of trapdoor algorithms ($\text{TrapGen}$, $\text{LWEGen}$, $\text{LWEInv}$), in case the secret vector is sampled uniformly at random and can thus be selected $s = F(r, H(r))$ involving a deterministic function $F$ and a cryptographic hash function $H$ modeled as a (quantum-) random oracle. This is a crucial ingredient of our construction and the resulting schemes. In particular, we achieve public and secret keys each consisting only of 1 polynomial. Hence, our construction improves upon previous proposals, where the public key contains at least $\log q$ polynomials (matrix dimension in [MP12] is $n \times n(1 + \lg q)$, see also [LPR13]), and is thus comparable with the public key size used in current state-of-the-art encryption schemes. This makes the usage of trapdoor based constructions more attractive for practice as it provides direct access to the secret and error vectors, which can be exploited in many different ways and at least for inspection.

**Implementation and Analysis.** In order to attest the conjectured efficiency of our scheme that we call LARA_{CPA} or LARA_{CCA}, we implement the (quantum-) random oracle variants of our CPA- and CCA-secure schemes in software. This
implementation is optimized with respect to the underlying architecture. To this end, we applied optimized techniques for discrete Gaussian sampling and FFT multiplication, the core elements governing the efficiency of the scheme. In particular, we adopt several optimizations for the polynomial representation and polynomial multiplication by use of efficient FFT/NTT operations. We implement our scheme and compare it with various schemes. For our reference implementation and \( n = 1024 \) (conservative parameters), we attest running times of 418 000 cycles for encryption and about 289 000 cycles for decryption in the CPA-secure setting. Thus, in comparison to the other schemes, we achieve by our improved trapdoor construction high message throughputs at low ciphertext expansion factors and at efficient running times and key sizes. The AVX-implementation is about twice as fast.

1.2 Acknowledgements

The work presented in this paper was performed within the context of the project P1 within the CRC 1119 CROSSING. We thank Douglas Stebila for his useful comments.

1.3 Organization

This paper is structured as follows. Section 2 provides the relevant background of our work. In Section 3 we introduce the A-LWE problem from [EDB15] and present our improvements to enhance the message throughput. In Section 4 a description of new trapdoor algorithms is proposed. The resulting encryption schemes are detailed in Section 5. In Section 6 we present our software implementation and experimental results.

2 Preliminaries

Notation We will mainly focus on polynomial rings \( R = \mathbb{Z}[X]/\langle X^n + 1 \rangle \) and \( R_q = \mathbb{Z}_q[X]/\langle X^n + 1 \rangle \) for integers \( q > 0 \) and \( n \) being a power of two. We denote ring elements by boldface lower-case letters e.g. \( \mathbf{p} \), whereas for vectors of ring elements we use \( \hat{\mathbf{p}} \) and upper-case bold letters for matrices (e.g., \( A \)). By \( \oplus \) we denote the XOR operator.

Discrete Gaussian Distribution We define by \( \rho : \mathbb{R}^n \to (0, 1] \) the \( n \)-dimensional Gaussian function

\[
\rho_{s,c}(\mathbf{x}) = e^{-\pi \cdot \| \mathbf{x} - \mathbf{c} \|^2 / s^2}, \quad \forall \mathbf{x}, \mathbf{c} \in \mathbb{R}^n.
\]

The discrete Gaussian distribution \( D_{\Lambda + c, s} \) is defined to have support \( \Lambda + \mathbf{c} \), where \( \mathbf{c} \in \mathbb{R}^n \) and \( \Lambda \subset \mathbb{R}^n \) is a lattice. For \( \mathbf{x} \in \Lambda + \mathbf{c} \), it basically assigns the probability \( D_{\Lambda + c, s}(\mathbf{x}) = \rho_{s}(\mathbf{x}) / \rho_{s}(\Lambda + \mathbf{c}) \).

Lattices. Throughout this paper we are mostly concerned with \( q \)-ary lattices \( \Lambda_q^+ (A) \) and \( \Lambda_q (A) \), where \( q = \text{poly}(n) \) denotes a polynomially bounded modulus.
and \( A \in \mathbb{Z}_q^{n \times m} \) is an arbitrary matrix. \( \Lambda_q^\perp(A) \) and \( \Lambda_q(A) \) are defined by
\[
\Lambda_q^\perp(A) = \{ x \in \mathbb{Z}^m \mid Ax \equiv 0 \mod q \} \\
\Lambda_q(A) = \{ x \in \mathbb{Z}^m \mid \exists s \in \mathbb{Z}^m \text{ s.t. } x = A^\top s \mod q \}.
\]

**Definition 1.** For any \( n \)-dimensional lattice \( \Lambda \) and positive real \( \epsilon > 0 \), the smoothing parameter \( \eta_\epsilon(\Lambda) \) is the smallest real \( s > 0 \) such that \( \rho_1(s) (\Lambda \setminus \{0\}) \leq \epsilon \).

**Lemma 1 ([Ban95, Lemma 2.4]).** For any \( s > 0 \) and \( T > 0 \), and any \( x \in \mathbb{R}^n \), we have
\[
P[\| (x, D_{\mathbb{Z}^n,s}) \| \geq T \cdot s \|x\|] < 2 \exp(-\pi \cdot T^2).
\]

**Lemma 2 ([GPV08, Theorem 3.1]).** Let \( \Lambda \subset \mathbb{R}^n \) be a lattice with basis \( S \), and let \( \epsilon > 0 \). We have \( \eta_\epsilon(\Lambda) \leq \| S \| \sqrt{\ln(2n (1 + \frac{1}{\epsilon})) \pi} \). In particular, for any function \( \omega(\sqrt{\log n}) \), there is a negligible \( \epsilon(n) \) for which \( \eta_\epsilon(\Lambda) \leq \| S \| \omega(\sqrt{\log n}) \).

**Corollary 1 ([DM14, Corollary 4]).** Let \( n \geq 4 \) be a power of two, \( q \geq 3 \) a power of 3, and set \( R_q = \mathbb{Z}_q[x]/(x^n + 1) \), then any nonzero polynomial \( t \in R_q \) of degree \( d < n/2 \) and coefficients in \( \{0, \pm 1\} \) is invertible in \( R_q \).

**Definition 2 (LWE Distribution).** Let \( n, m, q \) be integers and \( \chi_\epsilon \) be distribution over \( \mathbb{Z} \). By \( L_{n,m,q}^{\mathrm{LWE}} \) we denote the LWE distribution over \( \mathbb{Z}_q^{n \times m} \times \mathbb{Z}_q^m \), which draws \( A \leftarrow R \mathbb{Z}_q^{n \times m} \) uniformly at random, samples \( e \leftarrow R \mathbb{Z}_q \) and returns \((A, b^\top) \in \mathbb{Z}_q^{n \times m} \times \mathbb{Z}_q^m \) for \( s \in \mathbb{Z}_q^n \) and \( b^\top = s^\top A + e^\top \).

**Definition 3 (LWE Problem).** Let \( u \in \) be uniformly sampled from \( \mathbb{Z}_q^n \).
- The decision problem of LWE asks to distinguish between \((A, b^\top) \leftarrow L_{n,m,q}^{\mathrm{LWE}} \) and \((A, u^\top) \) for a uniformly sampled secret \( s \leftarrow R \mathbb{Z}_q^n \).
- The search problem of LWE asks to return the secret vector \( s \in \mathbb{Z}_q^n \) given an LWE sample \((A, b) \leftarrow L_{n,m,q}^{\mathrm{LWE}} \) for a uniformly sampled secret \( s \leftarrow R \mathbb{Z}_q^n \).

## 3 Augmented Learning with Errors

In this section, we give a description of the message embedding approach as proposed in [EDB15] and how it is used in order to inject auxiliary data into the error term of LWE samples. This feature represents the main building block of the generic encryption scheme from [EDB15], which allows to encrypt huge amounts of data without increasing the ciphertext size. In fact, it is even possible to combine this concept with the traditional one-time-pad approach in order to take the best from both worlds and hence increase the message size per ciphertext at almost no cost.

**Lemma 3 ([EDB15, Statistical]).** Let \( B \in \mathbb{Z}_p^{n \times m} \) be an arbitrary full-rank matrix and \( \epsilon = \text{negl}(n) \). The statistical distance \( \Delta(D_{\mathbb{Z}^m,r}, D_{\Lambda_q^\perp(B),r}) \) for uniform \( v \leftarrow R \mathbb{Z}_p^n \) and \( r \geq \eta_\epsilon(\Lambda_q^\perp(B)) \) is negligible.

**Lemma 4 ([EDB15, Computational]).** Let \( B \in \mathbb{Z}_p^{n \times m} \) be an arbitrary full-rank matrix. If the distribution of \( v \in \mathbb{Z}_p^n \) is computationally indistinguishable from the uniform distribution over \( \mathbb{Z}_p^n \), then \( D_{\Lambda_q^\perp(B),r} \) is computationally indistinguishable from \( D_{\mathbb{Z}^m,r} \) for \( r \geq \eta_\epsilon(\Lambda_q^\perp(B)) \).
3.1 Message Embedding

The proposed technique aims at embedding auxiliary data into the error term $e$ such that it still follows the required error distribution. In particular, Lemma 3 and 4 are used, which essentially state that a discrete Gaussian over the integers can be sampled by first picking a coset $A^{\perp}_q(B) = c + A^{\perp}_q(B)$ uniformly at random for any full-rank matrix $B \in \mathbb{Z}_p^{n \times m}$ and then invoking a discrete Gaussian sampler outputting a preimage $x$ for $c$ such that $B \cdot x \equiv c \mod p$ However, this requires the knowledge of a suitable basis for $A^{\perp}_q(B)$. In fact, the random coset selection can be made deterministic by means of a random oracle $H$ taking a random seed with enough entropy as input.

The fact that xor-ing a message $m$ to the output of $H$ does not change the distribution, allows to hide the message within the error vector without changing its target distribution. As a result, we obtain $e \leftarrow D^{A^{\perp}_q(B)}_{\eta(p)}$, which is indistinguishable from $D_{\mathbb{Z}_p^{n \times m}}$, for a random seed $\mu$ and properly chosen parameters (see Lemma 3 and Lemma 4). Subsequently, based on the message embedding approach the Augmented LWE problem (A-LWE) has been introduced, where A-LWE samples resemble ordinary LWE instances except for the modified error vectors. In particular, the A-LWE problem is specified with respect to a specific matrix $G$, which allows to efficiently sample very short vectors according to the discrete Gaussian distribution. We note that other choices are also possible as long as the parameter of the error vectors exceed the smoothing parameter of the associated lattice. We now give a generalized description of the A-LWE distribution using any preimage sampleable public matrix $B$.

**Definition 4 (Augmented LWE Distribution).** Let $n, n', m, m_1, m_2, k, q, p$ be integers with $m = m_1 + m_2$, where $aq \geq \eta_k(A^\perp(B))$. Let $H : \mathbb{Z}_q^n \times \mathbb{Z}_q^{m_1} \rightarrow \{0, 1\}^{n' \log p}$ be a cryptographic hash function modeled as random oracle. Let $B \in \mathbb{Z}_p^{n' \times m_2}$ be a preimage sampleable full-rank matrix (such as $B = G$ from [MP12]). For $s \in \mathbb{Z}_q^n$, define the A-LWE distribution $L^{A^{\perp}_{n, m_1, m_2, aq}}$ with $m \in \{0, 1\}^{n' \log p}$ to be the distribution over $\mathbb{Z}_q^{n \times m_2} \times \mathbb{Z}_q^m$ obtained as follows:

1. Sample $A \leftarrow R \mathbb{Z}_q^{n \times m}$ and $e_1 \leftarrow R \mathbb{Z}_q^{m_1 \times aq}$.
2. Set $v = \text{encode}(H(s, e_1) \oplus m) \in \mathbb{Z}_p^{n'}$.
3. Sample $e_2 \leftarrow R \mathbb{Z}_q^{A^{\perp}_{n, m_2, aq}}$.
4. Return $(A, b^\top)$ where $b^\top = s^\top A + e^\top$ with $e = (e_1, e_2)$.

We note that the Step 3 returns a discrete Gaussian that is distributed as $D_{\mathbb{Z}_q^{n \times m_2 \times aq}}$ following [EDB15, Computational]. In principal, for A-LWE one differentiates the decision problem decision A-LWE$_{n, m_1, m_2, aq}$ from the corresponding search problem search-s A-LWE$_{n, m_1, m_2, aq}$, as known from LWE. Furthermore, there exists a second search problem search-m A-LWE$_{n, m_1, m_2, aq}$, where a challenger is asked upon polynomially many A-LWE samples to find in polynomial time the message $m$ injected into the error vector. Note that the error distribution could also differ from the discrete Gaussian distribution. For instance, one could use the uniform distribution, for which one obtains similar results. All the proofs
from [EDB15] go through without any modifications, since the security proofs are not based on the choice of $B$.

**Theorem 1** (adapted [EDB15]). Let $n, n', m, m_1, m_2, q, p$ be integers with $m = m_1 + m_2$. Let $H$ be a random oracle. Let $aq \geq \eta \epsilon(\Lambda \perp q(B))$ for a real $\epsilon = \text{negl}(\lambda) > 0$ and preimage sampleable public matrix $B \in \mathbb{Z}_{p}^{n' \times m_2}$. Furthermore, denote by $\chi_s$ and $\chi_{e_1}$ the distributions of the random vectors $s$ and $e_1$ involved in each A-LWE sample. If $H_{\infty}(s, e_1) > \lambda$, then the following statements hold.

1. If search LWE$_{n,m,aq}$ is hard, then search-s A-LWE$_{n,m_1,m_2,aq}$ is hard.
2. If decision LWE$_{n,m,aq}$ is hard, then decision A-LWE$_{n,m_1,m_2,aq}$ is hard.
3. If decision LWE$_{n,m,aq}$ is hard, then search-m A-LWE$_{n,m_1,m_2,aq}$ is hard.

One easily notes, that these hardness results also hold for the ring variant (see [ABBK17]). We remark that for encryption schemes the secret $s$ is always resampled such that $H(s)$ suffices to output a random vector and the complete bandwidth of $e$ is exploited for data to be encrypted.

### 3.2 Improved Message Embedding

For the sake of generality, we used in all our statements an abstract matrix $B \in \mathbb{Z}_{p}^{n' \times m}$ for integers $p, n'$, and $m$. This is used to embed a message into the error term via $e_2 \leftarrow R D_{\Lambda_{\perp}^{c}(B),aq}$, where $v = \text{encode}(H(\text{seed}) \oplus m) \in \mathbb{Z}_{p}^{n'}$ is uniform random. However, we can specify concrete matrices that optimize the amount of information per entry with respect to the bound given in Lemma 2. We propose several techniques in order to enhance the message throughput per discrete Gaussian vector. These techniques could also be applied to the error vector involved in the A-LWE distribution. In other words, we aim at choosing an appropriate preimage sampleable full-rank matrix $B \in \mathbb{Z}_{p}^{n' \times m}$ such that $n' \cdot \log p$ is maximized. For now, we will focus on how to apply this technique to the different encryption schemes and omit the term $e_1$ when invoking the random oracle, since the secret $s \in \mathbb{Z}_{q}^{n}$ is always resampled in encryption schemes and hence provides enough entropy for each fresh encryption query. The first approach is based on a method used to construct homomorphic signatures in [BF11]. We also propose a simpler approach that avoids such complex procedures while entailing the same message throughput.

**Intersection Method.** The intersection method as proposed in [BF11] considers two $m$-dimensional integer lattices $A_1$ and $A_2$ such that $A_1 + A_2 = \mathbb{Z}^m$, where addition is defined to be element-wise. Therefore, let $m_1$ and $m_2$ be two messages, where $m_1$ and $m_2$ define a coset of $A_1$ and $A_2$ in $\mathbb{Z}^m$, respectively. As a result, the vector $(m_1, m_2)$ defines a unique coset of the intersection set $A_1 \cap A_2$ in $\mathbb{Z}^m$. By the Chinese Remainder theorem one can compute a short vector $t$ such that $t = m_1 \mod A_1$ and $t = m_2 \mod A_2$ using a short basis for $A_1 \cap A_2$. In fact, it is easy to compute any vector $t$ that satisfies the congruence relations. Subsequently, by invoking a preimage sampler one obtains a short vector from $A_1 \cap A_2 + t$. 

Lattices of the Form $p\mathbb{Z}^m$. One realizes that for a given parameter $\alpha q$ for the distribution of the error vector one can be much more efficient, if one considers only the lattice $L_p(I) = p\mathbb{Z}^m$. In this case, the message space is simply defined by the set $M = \mathbb{Z}^m / L_p(I) \cong \mathbb{Z}_p^m$. When comparing with the previous approach, for instance, it is only required to increase $p$ by a factor of 2 in order to obtain the same message throughput $m \log 2p = m \cdot (\log p + 1)$. Furthermore the decoding and encoding phase is much faster, since encoding requires only to sample $e \leftarrow D_{b+p\mathbb{Z}^m,\alpha q}$ for $b = H(r) \oplus m$ using fast discrete Gaussian samplers such as the Knuth-Yao algorithm or efficient lookup tables. Decoding is performed via $H(r) \oplus (e \mod p)$. Optimizing the message throughput requires to increase $p$ such that $\eta e(A) \leq p \cdot \text{const} \leq \alpha q$ still holds for $\text{const} = \sqrt{\ln(2(1 + 1/\epsilon))}/\pi$. Doing this, one can embed approximately $m \cdot \log p$ bits of data, which almost coincides with the min-entropy of a discrete Gaussian with parameter $\alpha q$, since $\text{const} \approx 4.7$. Therefore, one prefers to choose a parameter $\alpha q = p \cdot \text{const}$ with $p = 2^i$ and integer $i > 0$ in order to embed $i$ bits of data into the error term.

Uniform Error. For uniformly distributed errors one can directly employ the output of the random function $H(\cdot)$ as the error term. More specifically, suppose $e \in \{-p, p\} \cap \mathbb{Z}^m$, then let $H(\cdot) : \{0, 1\}^* \rightarrow [\{-p, p\} \cap \mathbb{Z}^m]$ be a random function (e.g. RO) such that $e \leftarrow \text{encode}(H(r) \oplus m)$ for $m \in \{0, 1\}^m \log_2(2p)$. As a result, one can use the full bandwidth of the error term and inject $m \log_2(2p)$ message bits.

4 New Trapdoor Algorithms for Ideal-Lattices

In [EB14] a generic approach of how to instantiate the trapdoor construction is given that allows to retrieve the error term and the secret vector from A-LWE instances. However, the number of public key polynomials is with $\tilde{m} + k$ polynomials where $k = \lceil \log q \rceil$ rather large and hence not suitable for practice. In fact, the trapdoor constructions [EB14,MP12] require at least 2 public key polynomials in order to generate signatures. For encryption, one requires even more as the LWE inversion algorithm has to efficiently recover the correct secret. Thus, a new approach is needed in order to tackle this issue.

In this section, we give new trapdoor algorithms and show how to reduce the size of the public key to just 1 polynomial. This is due to the fact that we can select the secret vector in A-LWE instances to be of the form $s = F(r, H_1(r))$ for a deterministic function $F(\cdot)$, where $r$ is a random bit string and $H_1$ is a cryptographic hash function modeled as RO. Remarkably, the secret key consists only of 1 polynomial, which improves upon the construction from [MP12,EB14]. We start with a description of our new trapdoor algorithms in the ring setting $K = (\text{TrapGen}, \text{LWEGen}, \text{LWEInv})$. Lemma 5 shows that TrapGen outputs a public key that is computationally indistinguishable from uniform random. In order to use tags for CCA-secure constructions, we need to modify the way, in which tags are applied.
4.1 Construction of Efficient Trapdoors for A-LWE

We present new trapdoor algorithms for public key generation (TrapGen), ring-LWE generation (LWEGen) and inversion (LWEInv). These algorithms will serve to instantiate our new encryption scheme from ring A-LWE. For the sake of simplicity, we only consider the case where $q = p^k$, where $p$ is any positive (prime) integer.

1. **TrapGen($1^n$)**: Let $q = p^k$ for a prime integer $p > 0$. Let further $g = p^{k-1}$. The system parameters are two uniform random polynomials $a_1, a_2 \in R_q$ (e.g. sampled from a seed). Sample 2 random polynomials $r_i$ according to $D_{Z_n, \text{sec}}$ for $i \in \{1, 2\}$. The public and secret keys are given by $pk := a_3, sk = [r_1, r_2]$ with

$$A = \begin{bmatrix} a_1, a_2, g - (a_1 \cdot r_1 + a_2 \cdot r_2) \\ a_3 \end{bmatrix} \in R_q^3.$$  

If a tag $t_u$ is applied, we obtain $A_u$ via $t_u \cdot g$ (see below).

2. **LWEGen($1^n$)**: In order to generate an (A-)LWE instance, we let $H_1$ be a cryptographic hash function modeled as a random oracle. For $A$ we generate ring-LWE instances

$$[b_1, b_2, b_3] = [a_1, a_2, g - (a_1 \cdot r_1 + a_2 \cdot r_2)] \cdot s + \hat{e} \in R_q^3.$$  

Each coefficient of $s \in R_q$ is of the form

$$s_i = c_{i,0} + c_{i,1} \cdot p + ... + c_{i,k-1} \cdot p^{k-1}$$  

for $c_{i,j} \in \{0, ..., p - 1\}$ and $i \in \{1, ..., n\}$, where $c_{i,0} \leftarrow R \{0, ..., p - 1\}$ is sampled uniformly at random. Then, invoke $d = H(c_{1,0}, ..., c_{n,0}) \to Z_{p^{k-1}}^n$ and set $s_i = c_{i,0} + p \cdot d_i$.

- For the special case $q = 2^k$, the binary number $c_{i,0}$ corresponds to the least significant bit of the coefficient $s_i$. That is $\text{LSB}(s_i) \leftarrow R \{0, 1\}$, where $\text{LSB}$ denotes the least significant bit. Then, in order to set the remaining bits of $s_i$ invoke $d = H_1(\text{LSB}(s_1), ..., \text{LSB}(s_n)) \in Z_{p^{k-1}}$. Finally, determine $s_i = \text{LSB}(s_i) + 2 \cdot d_i \in Z_q$ by appending the bit $c_{i,0}$ to $d_i$.

The error polynomials $e_i$ can now be sampled from the discrete Gaussian distribution $D_{Z_n, \alpha q}$, where $1 \leq i \leq 3$ and $\alpha q > 0$.

3. **LWEInv($b, sk$)**: We first compute

$$v = g \cdot s + t = b_3 + b_1 \cdot r_1 + b_2 \cdot r_2,$$

where $t$ is a some small error.

The closest integer $c_{i,0} p^{k-1}$ to each coefficient $v_i$ is recovered. This is possible if $|t_i| < p^{k-1}/2$. In particular, we recover $c_{i,0}$ via

$$c_{i,0} = \lfloor v_i/p^{k-1} \rfloor \mod p \text{ for } 0 \leq i < n.$$
• For $q = 2^k$, we have $c_{i,0} = \text{LSB}(s_i) = \lfloor v_i/2^{k-1} \rfloor \mod 2$.
  Once having recovered all $c_{i,0}$, the hash function is invoked $d = H_1(c_{1,0}, \ldots, c_{n-1,0}) \in \mathbb{Z}_{p^{k-1}}$ such that $s_i = c_{i,0} + d_i \cdot p$. The error vector is subsequently retrieved via $\hat{e} = \hat{b} - A \cdot s$.

Remark 1. For odd $q$ and small secrets, we can instead set $g = (q - 1)/2$. The most significant bits do not vanish but wrap around modulo $q$. We note, that the case $q = 2^k$ is very efficient due to cheap sampling and modulo operations.

Lemma 5. Let $a_1, a_2 \in \mathbb{R}_q$ be uniform random polynomials and $r_1, r_2$ be sampled according to $D_{\mathbb{R}, \alpha q} = D_{\mathbb{Z}_n, \alpha q}$ (via the coefficient embedding) for $\alpha q > 2 \sqrt{n}$. The public key $A = [a_1, a_2, a_1 \cdot r_1 + a_2 \cdot r_2]$ is computationally indistinguishable from uniform.

Proof. For simplicity, we can assume that $a_1$ is a unit in $\mathbb{R}_q$, since the ring of units $\mathbb{R}_q^\times$ represents a non-negligible subset of $\mathbb{R}_q$ for the rings in consideration. Then $A = a_1 \cdot [1, \bar{a}, \bar{a} \cdot r_2 + r_1]$, where $[\bar{a}, \bar{a} \cdot r_2 + r_1]$ is a ring-LWE instance with a uniform random polynomial $\bar{a} = a_1^{-1} a_2$, since $a_2$ is uniform random. As a result and due to the independence of $a_1$ from $a_2$ the claim follows.

Lemma 6 (Correctness). For $q = p^k$, error polynomials $e_i$ and secret key polynomials $r_j$, the algorithm $\text{LWEInv}(\hat{b}, sk)$ correctly inverts the (A-)LWE instance, if

$$\|e_3 + e_1 \cdot r_1 + e_2 \cdot r_2\|_{\infty} < p^{k-1}/2.$$ 

Proof. The inversion algorithm computes

$$b_3 + b_1 \cdot r_1 + b_2 \cdot r_2 \mod q = g \cdot s + e_3 + e_1 \cdot r_1 + e_2 \cdot r_2 \mod q$$

$$= p^{k-1} \cdot s + e_3 + e_1 \cdot r_1 + e_2 \cdot r_2 \mod q$$

$$= p^{k-1} \cdot \begin{bmatrix} c_{1,0} \\ \vdots \\ c_{n,0} \end{bmatrix} + e_3 + e_1 \cdot r_1 + e_2 \cdot r_2 \mod q$$

So, if $\|e_3 + e_1 \cdot r_1 + e_2 \cdot r_2\|_{\infty} < p^{k-1}/2$, then we clearly can recover $c_{i,0}$ of each coefficient. From the coefficients we can recover $s$ and $e_j$ and thus the message.

Tagging the public key (in order to achieve CCA security) in the ring setting is accomplished similar to [MP12, EDB15], but with some practical obstacles to be solved for decryption. This is due to the random oracle instantiation, which prevents from recovering the tag $t_u$ in a straightforward way.
because the inversion algorithm only recovers \( c_{i,0} \) (for \( q = p^k \)) of the coefficients from \( t_u \cdot s \). However, via a trick we can circumvent this obstacle in a computationally indistinguishable way. This is mainly possible, since \( t_u \) is a unit and multiplication with a uniform random polynomial is again uniform. Thus, we can instead generate \( t_u \cdot s := c_{i,0} + p \cdot d_i \) in \( \text{LWEGen} \) and cancel out \( t_u \) from it via its inverse when \( s \) is required. Here, we denote \( A_u = [a_1, a_2, t_u \cdot g - (a_1 r_1 + a_2 r_2)] \) in accordance to Section 4.

5 Public Key Encryption

In order to build a public key encryption scheme we need to combine the trapdoor construction described in Section 4 with the message embedding approach from Section 3. The main idea is to inject data to be encrypted into the error polynomials from \( \text{LWEGen} \). To this end, we need the error terms to be partially deterministic and simultaneously look random by use of a random oracle.

Fig. 1: Description of the CPA-secure Encryption Scheme.

We now give a description of our new CPA-secure public key encryption scheme. Thus, let \( s = w \cdot \sqrt{\ln (2n (1 + \frac{1}{z}))} / \pi \) for an integer \( w > 2 \). Hence, we embed the message into the cosets of the lattice \( \mathcal{L} = \mathbb{Z}^n \) (see Section 3.2).

For key generation, the CPA-secure scheme just invokes \( \text{TrapGen} \). For a compact scheme, we let the uniform random polynomials \( a_1, a_2 \) be generated from a large enough seed \( \in \{0, 1\}^λ \) ensuring \( n(\lambda) \) classical bits. Here \( G \) is
instantiated as a random oracle, which in practice can be replaced by pseudorandom generators such as $\text{Shake}$. The encryption function works similar to $\text{LWEGen}$ with the main difference that $H$ outputs the additional random vectors $v_i$ used to mask the message and to generate the error polynomials via Lemma 3. The $\text{Encode}$ and $\text{Decode}$ routines are used to translate between bit strings and vectors/polynomials. The decryption routine invokes $\text{LWEInv}$ to recover the error polynomials and the secret $s$. Finally, all steps from the encryption function are reversed such that the message is unmasked again.

Remark 2. For $q = 2^k$, $t_i = \text{Encode}(m_i) + v_i \mod 2$ is equivalent to $t_i = \text{Encode}(m_i \oplus h_i)$, where $h_i := \text{Decode}(v_i)$. This complies with the representation of Section 3, when defining the ALWE problem. We can also directly generate $v_i$ as a bit string during encryption without the need for conversion.

In the standard IND-CPA security game the adversary is challenged to correctly guess the bit $b$ with non-negligible advantage given two distinct messages of his/her choice.

Experiment $\text{Exp}_{\text{Ind-CPA}}(n)$

\[
(\text{pk}, \text{sk}) \leftarrow \text{KGen}(1^k)
\]

\[
(\mu_0, \mu_1) \leftarrow \mathcal{A}(\text{CHOOSE}, \text{pk})
\]

\[
c_b \leftarrow \text{Enc}_{\text{pk}}(\mu_b) \quad \text{for} \quad b \leftarrow_R \{0, 1\}
\]

\[
b' \leftarrow \mathcal{A}(\text{GUESS}, c_b)
\]

Output 1 iff

1. $b' = b$
2. $|\mu_0| = |\mu_1|$

We now state the main theorem of this section, which can be extended to the quantum random oracle case. By $\text{lb-RLWE}$ we define the problem of finding low order bits in ring-LWE instances.

**Theorem 2.** Let $\text{lb-RLWE}$ be defined as in Lemma 7. In the random oracle model, assume that there exists a PPT-adversary $\mathcal{A}$ against the scheme with $s \geq w \cdot \sqrt{\ln (2n \left(1 + \frac{1}{2}\right)) / \pi}$, then there exists a reduction $\mathcal{M}$ that breaks $\text{ring-LWE/ring-ALWE}$ such that

\[
\text{Adv}_{\text{LARA}}^{\text{CPA}}(\mathcal{A}) \leq 3\text{Adv}_{\text{lb-RLWE}}^{\text{dec}}(\mathcal{M}) + \text{Adv}_{\text{lb-RLWE}}^{\text{dec}}(\mathcal{M}) + q_H/p^n.
\]

**Proof.** We proceed via a sequence of hybrids and show that the ciphertext is pseudorandom under any of the computational assumptions, namely ring-LWE or ring-ALWE, where latter is itself based on ring-LWE. Let $\mathcal{H}_0$ be the real IND-CPA game. In the first hybrid $\mathcal{H}_1$, we replace $a_3$ by a uniform random polynomial. If there exists a distinguisher that can distinguish $\mathcal{H}_0$ from $\mathcal{H}_1$, then there exists a reduction $\mathcal{M}_0$ that breaks decision ring-LWE ($\text{dec-RLWE}$). Thus, $\text{Adv}_{\mathcal{H}_0 \mathcal{H}_1}(\mathcal{A}) \leq \text{Adv}_{\text{dec-RLWE}}^{\text{dec}}(\mathcal{M}_0)$. In the second hybrid $\mathcal{H}_2$, we change the random oracle output $(v_1, v_2, v_3, d)$ of $H(c_0)$ by uniform random values and thus also $t_i$ for $1 \leq i \leq 3$. A PPT adversary can only distinguish $\mathcal{H}_1$ from $\mathcal{H}_2$, if it queries $H$ on $c_0$ (see below). But then, a
Lemma 7. Let \( q = O(n) \) and \( \ell \) the error size. Suppose there exists a PPT algorithm \( \mathcal{S} \) that can output the low order bits of the secret in ring-LWE instances (\( \mathsf{lb} - \mathsf{RLWE} \) problem), then there exists a PPT algorithm \( \mathcal{B} \) that breaks the search version of ring-LWE.

Proof. Suppose there exists such an algorithm. For simplicity, let \( p \) be co-prime to \( q \). The ring-LWE samples \( \{(a_i, b_i := a_i \cdot s + e_i \mod q)\} \) define the problem instance. \( \mathcal{B} \) is challenged to find \( s \). With high probability, there exists an invertible element \( a_j \in \mathbb{R}_q \) (see e.g. [Pei15]). Taking any other sample, e.g. \((a_1, b_1 := a_1 \cdot s + e_1 \mod q)\), we can construct samples \( b_i^{(0)} := (a_j^{-1} a_i)(e_j + d) + e_i \mod q \) with \( e_i + d \) as the secret and \( i \neq j \) [ACPS09]. Here, the term \( d \) is filled with the tail bound at each coefficient such that all coefficients of \( e_j + d \) are positive. Finding \( s \) is equivalent to recovering \( (e_j + d) := e_j^{(0)} = c_0 + p \cdot c_1 + \ldots + p^{\ell-1} c_{\ell-1} \) with \( c_i \in \mathbb{Z}_p^* \) for some small \( \ell < k \). The first input to \( \mathcal{S} \) is therefore \( (a_i^{(0)} := a_j^{-1} a_i, b_i^{(0)}) \) which outputs \( c_0 \) in polynomial time by assumption. In the second iteration the input is modified to \((a_i^{(1)}, b_i^{(1)}) \) with \( a_i^{(1)} := p \cdot a_i^{(0)} \), \( b_i^{(1)} := b_i^{(0)} - a_i^{(0)} \cdot c \mod q = a_i^{(0)} \cdot (p \cdot c_1 + \ldots + p^{\ell-1} c_{\ell-1}) + e_i \mod q = (p \cdot a_i^{(0)}) \cdot (c_1 + \ldots + p^{\ell-2} c_{\ell-1}) + e_i \mod q \) and secret \( e_j^{(1)} := (c_1 + \ldots + p^{\ell-2} c_{\ell-1}) \). Then, \( \mathcal{S} \) outputs \( c_1 \) by assumption. Analogously, via \( (a_i^{(t)} := p^t \cdot a_i^{(0)}, b_i^{(t)} := b_i^{(t-1)} - a_i^{(t-1)} \cdot c^{(t-1)}) \) as input
instances to $S$ the algorithm $B$ obtains all $c_i$ for $0 \leq t \leq \ell - 1$, recovers $e_j + d = c_0 + p \cdot c_1 + \ldots + p^{\ell-1}c_{\ell-1}$ and thus $s$ (after $\ell$ iterations) solving search – RLWE. Adding small errors to $a_i^{(t)}$ generalizes the proof to all $p, q$.

5.1 CCA-secure Encryption

In order to obtain CCA-security, there exist 2 approaches. The first approach just requires to turn a CPA-secure public key encryption scheme via the Fujisako-Okamoto transform [FO99] into a CCA-secure hybrid encryption scheme. This can indeed be made very efficiently, where the symmetric key cipher could be instantiated by a random oracle or pseudorandom function (such as Shake). The other approach is realized based on the so-called tag approach, where a random tag [MP12, ABB10, PV08] is applied to the public key prior to encryption, i.e. we have $A_u = [a_1, a_2, t_u \cdot g - (a_1 r_1 + a_2 r_2)]$. This has been realized in several works such as [MP12, EDB15]. To this end, a large tag space $T$ has to be defined, out of which the tag is drawn uniformly at random. An element is called a tag, if it is a unit in the ring and satisfies the unit difference property. That is, for two units $u, v \in T$ the difference $u - v$ is again a unit. Beside of these properties, a further objective is to specify efficient algorithms that allow to sample elements from $T$ uniformly at random. In fact, for $q = 3^k$ the tag space may be defined to consist of binary polynomials of degree smaller than $n/2$ such that it satisfies the unit difference property as per Corollary 2. Thus, it suffices to sample binary strings of length $n/2$ bits and map them to the corresponding binary polynomial of degree smaller than $n/2$. In Section 4.1 we explained how to generate $t_u \cdot s$ such that we can recover $s$. Using the framework from [EDB15] we give a CCA-secure scheme in Appendix A.

Corollary 2 (Unit Difference Property). Let the tag space be defined as $T = \{a_0 + a_1 \cdot x + \ldots + a_{n/2-1} \cdot x^{n/2-1} \mid \text{for } a_i \in \{0, 1\}\} \setminus \{0\}$. Then, any tag $u \in T$ satisfies the unit difference property.

Proof. Any two elements $u_1, u_2 \in T$ are invertible as per Corollary 1. Since both tags of degree at most $n/2 - 1$ have coefficients in $\{0, 1\}$, the difference $u_1 - u_2$ has coefficients in $\{0, \pm 1\}$; thus invertible as per Corollary 1.

6 Software Implementation and Performance Analysis

At the implementation front we consider several optimizations and present an overview of the main ingredients. The error polynomials are generated as $e_i \leftarrow D_{\rho \mathbb{Z}_p^\Lambda + v_i \cdot \alpha q}$ for uniform random cosets $v_i$ following Lemma 3. This is realized with the aid of lookup tables, where almost $0.99$ of the probability mass is concentrated on the 10 mid elements. Furthermore, we can use buckets for the 10 mid elements such that one call suffices to obtain a sample in $0.99$ of all cases. In general, we find the right element after around 2 table lookups. By this technique we can build an efficient discrete Gaussian sampler. We instantiate the random oracle $H(\cdot)$, when encrypting messages, by an efficient and secure pseudo-random generator such as Salsa20 or Shake\(^1\).

\(^1\) KeccakCodeProject: github.com/gvanas/KeccakCodePackage/
The secret key might consist of uniform random elements deduced from a seed and \( pk \). We refer to the table below for a description of parameters in use.

Fig. 2: Experimental results from our reference implementation.

where splLWE\_CCA provides only 128 bits of security. LARA has very small ciphertext expansion factors represented by a very low ratio of the ciphertext size per message bit. The number of cycles per encrypted message bit as well as its absolute performance and key sizes are very competitive for the CPA and CCA secure schemes. For instance, we are able to encrypt 2 bits per entry for \( q = 2^{15} \) or \( q = 2^{14} \) resulting in 414 586 cycles for encryption or 67 cycles per message bit. In order to estimate the security we used the LWE estimator\(^2\).

A  CCA-secure Encryption with Tags

Let \( q = 3^k \) and \( T \) define the tag space containing binary polynomials of degree less than \( n/2 \).

**LARA\textsubscript{CCA}.KGen : (1')**

1: \((sk, pk) \leftarrow \text{TrapGen}(1^k)\)
2: We replace \( a_1, a_2 \) in the public key with the seed generating those elements, i.e. \( pk = (\text{seed}, a_3) \), where \( a_3 = (a_1 \cdot r_1 + a_2 \cdot r_2) \).

**LARA\textsubscript{CCA}.Enc(pk, (m_1, m_2, m_3) \in \{0,1\}^{3n \log w})**

1: \( a_1, a_2 \leftarrow G(\text{seed}) \)
2: \( t_u \in T \)
3: \( c_0 = (c_1,0, \ldots, c_{n-1},0) \leftarrow Z^n_{\ell} \)
4: \( (v_1, v_2, v_3), d \leftarrow H(c_0) \in Z^n_{\ell} \times Z_{p-1}^n \)
5: \( t_u \cdot s = c_0 + p \cdot d \)
6: \( s := t_u^{-1} \cdot (c_0 + p \cdot d) \)
7: \( t_i = \text{Encode}(m_i) + v_i \mod w \text{ for } 1 \leq i \leq 3 \)
8: \( e_i \leftarrow D_{t_i + wZ^n_{\ell}} \text{ for } 1 \leq i \leq 3 \)
9: \( b_i = a_i \cdot s + e_i \text{ for } i = 1, 2 \)
10: \( b_3 = t_u \cdot s \cdot g - a_3 \cdot s + e_3 \)
11: \( h = H(s, t_u, \hat{e}) \)
12: Output \( u, h, b = (b_1, b_2, b_3) \).

**LARA\textsubscript{CCA}.Dec(sk, (u, h, \hat{b}) \in \{0,1\}^{n/2} \times \{0,1\}^3 \times \mathbb{R}_{\lambda}^3)**

1: \( a_1, a_2 \leftarrow G(\text{seed}) \)
2: \((t_u,s := c_0 + p \cdot d, e_1, e_2, e_3) \leftarrow \text{LWEInv}'(sk, \hat{b})\)
3: \((v_1, v_2, v_3), d \leftarrow H(c_0) \in \{0,1\}^{3n \log w} \times Z_{p-1}^n \)
4: if \( h = H(s, t_u, \hat{e}) \land \| \hat{e} \| \leq \sqrt{3n} \cdot s \)
5: \( t_i = e_i \mod w \text{ for } 1 \leq i \leq 3 \)
6: \( m_i = \text{Decode}(t_i - v_i \mod w) \)
7: Output \( (m_1, m_2, m_3) \)

Fig. 3: Description of the CCA-secure Encryption Scheme.

**Remark 3.** We note that in the encryption routine we have \((t_u \cdot g - a_3) \cdot s + e_3 = t_u \cdot s \cdot g - a_3 \cdot s + e_3\). Furthermore, the trapdoor inversion algorithm \( \text{LWEInv}' \) computes the same quantities as \( \text{LWEInv} \) with the difference that it also deduces \( t_u \) from \( u \) via the coefficient embedding. Once \( t_u \cdot s \) is recovered, one can compute \( s \) and thus \( \hat{e} = b - A_u \cdot s \) (see Section 4).
A.1 Chosen Ciphertext Security and Variants

We recall the definitions of (replayable) chosen ciphertext security of encryption schemes. Let $E = (KGen, Enc, Dec)$ be a public key encryption scheme and consider the following experiments for $atk \in \{cca1, cca2, rcca\}$:

**Experiment $Exp_{E,A}^{ind-atk}(n)$**

$(pk, sk) \leftarrow KGen(1^k)$

$(\mu_0, \mu_1) \leftarrow A^{Dec}(\text{CHOOSE}, pk)$

$c_0 \leftarrow Enc(pk)(\mu_b)$ for $b \leftarrow \{0, 1\}$

$b' \leftarrow A^{O_2(\cdot)}(\text{GUESS}, c_b)$

Output 1 iff

1. $b' = b$
2. $|\mu_0| = |\mu_1|$
3. $c_b$ was not queried to $O_2$

If $A$ queries $O_2(c)$, and
- if $atk = cca1$, then return $\perp$.
- if $atk = cca2$, then return $Dec(sk, c)$.
- if $atk = rcca$ and $Dec(sk, c) \notin \{\mu_0, \mu_1\}$, then return $Dec(sk, c)$.
- Otherwise, return $\perp$.

The security of the scheme directly follows from the framework as described in [EDB15].
